## MOTIVATION

Although Pandas has a spot-on interface and it is full of useful functionalities, it lacks performance and scalability. For example, it is hard to decipher intensive intraday data such as Options data or S&P500 constituents tick-by-tick data using Pandas.

Another issue I have encountered is, often, the research is done using Python, because it has such tools as Pandas, but the execution in production is in C++ for its efficiency, reliability and scalability. Therefore, there is this translation, or sometimes a bridge, between research and executions.

Also, in this day and age, C++ needs a heterogeneous data container. Mainly because of these factors, I implemented the C++ DataFrame.

*This library could still have more functionalities compared with Pandas. I welcome all contributions from people with expertise, interest, and time to do it. I will add more functionalities from time to time, but currently I don't have much free time.*

**Views** were recently added. This is a very interesting/useful concept that even Pandas doesn't have it currently. A view is a slice of a DataFrame that is a reference to the original DataFrame. It appears exactly the same as a DataFrame, but if you modify any data in the view, the original DataFrame will also be modified.

There are certain things you cannot do in views. For example, you cannot add to delete columns, extend the index column, ...

For more understanding, look at this document below and/or the test files.

## CODE STRUCTURE

The DataFrame library is almost a header-only library with a few small source files exceptions, *HeteroVector.cc* and *HeteroView.cc*. Also there is *DateTime.cc*.

Starting from the root directory;

*include* directory contains most of the code. It includes *.h* and *.tcc* files. The latter are C++ template code files. The main header file is *DataFrame.h*. It contains the entire DataFrame object and its interface. There are comprehensive comments for each interface call in that file. The rest of the files there will show you how the sausage is made.

*src* directory has a few source files, as explained above, make-files, and test program source files. The main test source file is *datasci\_tester.cc*. It contains test cases for all functionalities of DataFrame. It is not in a very organized structure. I plan to make the test cases more organized.

## BUILD INSTRUCTIONS

### USING PLAIN MAKE AND MAKE-FILES

Go to the root of the repository, where license file is, and execute *build\_all.sh*. This will build the library and test executables for Linux flavors.

### USING CMAKE

Please see README file. Thanks to [@justinjk007](#), you should be able to build this in Linux, Windows, Mac, and more

## EXAMPLE

This library is based on a heterogeneous vector. The heterogeneity is achieved by using static STL or STL-like vectors. Since C++ is a strongly typed language, you still have to know your column types per container at compile time. You can add more columns with different types at any time to your container, but when analyzing the data at any given time you must know the column types.

This is an example of how to create a DataFrame, load data, and run an operation on it:

```
// Defines a DataFrame with unsigned long index type that used std::vector
typedef DataFrame<unsigned long, std::vector> MyDataFrame;

MyDataFrame df;
std::vector<int> intvec = { 1, 2, 3, 4, 5 };
std::vector<double> dblvec = { 1.2345, 2.2345, 3.2345, 4.2345, 5.2345 };
std::vector<double> dblvec2 = { 0.998, 0.3456, 0.056, 0.15678, 0.00345, 0.923,
0.06743, 0.1 };
std::vector<std::string> strvec = { "Col_name", "Col_name", "Col_name", "Col_name",
"Col_name" };
std::vector<unsigned long> ulgvec = { 1UL, 2UL, 3UL, 4UL, 5UL, 8UL, 7UL, 6UL }
std::vector<unsigned long> xulgvec = ulgvec;

// This is only one way of loading data into the DataFrame. There are
// many different ways of doing it. Please see DataFrame.h and datasci_tester.cc
int rc = df.load_data(std::move(ulgvec),
    std::make_pair("int_col", intvec),
    std::make_pair("dbl_col", dblvec),
    std::make_pair("dbl_col_2", dblvec2),
    std::make_pair("str_col", strvec),
    std::make_pair("ul_col", xulgvec));
// Sort the Frame by index
df.sort<MyDataFrame::TimeStamp, int, double, std::string>();
//Sort the Frame by column "dbl_col_2"
df.sort<double, int, double, std::string>("dbl_col_2");

// A functor to calculate mean, variance, skew, kurtosis, defined in DFVisitors.h file
StatsVisitor<double> stats_visitor;
// Calculate the stats on column "dbl_col"
df.visit<double>("dbl_col", stats_visitor);
```

### View Example:

```
std::vector<unsigned long> idx =
    { 123450, 123451, 123452, 123450, 123455, 123450, 123449 };
std::vector<double> d1 = { 1, 2, 3, 4, 5, 6, 7 };
std::vector<double> d2 = { 8, 9, 10, 11, 12, 13, 14 };
std::vector<double> d3 = { 15, 16, 17, 18, 19, 20, 21 };
std::vector<double> d4 = { 22, 23, 24, 25 };
std::vector<std::string> s1 = { "11", "22", "33", "xx", "yy", "gg", "string" };
MyDataFrame df;

df.load_data(std::move(idx),
    std::make_pair("col_1", d1),
    std::make_pair("col_2", d2),
    std::make_pair("col_3", d3),
    std::make_pair("col_4", d4),
    std::make_pair("col_str", s1));

typedef DataFrameView<unsigned long> MyDataFrameView;

MyDataFrameView dfv = df.get_view_by_loc<double, std::string>({ 3, 6 });

dfv.get_column<double>("col_3")[0] = 88.0;
std::cout << "After changing a value on view: "
```

```
<< dfv.get_column<double>("col_3")[0]
<< " == " << df.get_column<double>("col_3")[3]
<< std::endl;
```

For more code examples see file *datasci\_testr.cc*

## TYPES

```
using size_type = std::vector<DataVec>::size_type;
```

size\_type is the size type

---

```
using TimeStamp = TS;
```

TimeStamp is the type of the index column

---

```
using TSVec = std::vector<TS>;
```

TSVec is the type of the vector containing the index column

---

```
enum class nan_policy : bool {  
    pad_with_nans = true,  
    dont_pad_with_nans = false  
};
```

Enumerated type of Boolean type to specify whether data should be padded with NaN or not

---

```
enum class sort_state : bool {  
    sorted = true,  
    not_sorted = false  
};
```

Enumerated type of Boolean type to specify whether data is sorted or not

---

```
template<typename T>  
struct Index2D {  
    T begin {};  
    T end {};  
};
```

It represents a range with begin and end within a continuous memory space

---

```
enum class shift_policy : unsigned char {  
    down = 1, Shift/rotate the content of all columns down,  
               keep index unchanged  
    up = 2,   Shift/rotate the content of all columns up,  
               keep index unchanged  
};
```

This policy is relative to a tabular data structure  
There is no right or left shift (like Pandas), because columns in DataFrame have no ordering. They can only be accessed by name

---

```
enum class fill_policy : unsigned char {  
    value = 1,  
    fill_forward = 2,  
    fill_backward = 3,
```

```

linear_interpolate = 4, Using the index as X coordinate
linear_extrapolate = 5 Using the index as X coordinate
};

```

This policy determines how to fill missing values in the DataFrame

value: Fill all the missing values, in a given column, with the given value.

fill\_forward: Fill the missing values, in a given column, with the last valid value before the missing value

fill\_backward: Fill the missing values, in a given column, with the first valid value after the missing value

linear\_interpolate:

linear\_extrapolate:

Use the index column as X coordinate and the given column as Y coordinate

And do interpolation/extrapolation as follows:

$$Y = Y1 + \frac{X - X1}{X2 - X1} * (Y2 - Y1)$$

---

```

enum class drop_policy : unsigned char {
    all = 1,          Remove row if all columns are nan
    any = 2,          Remove row if any column is nan
    threshold = 3     Remove row if threshold number of columns are nan
};

```

This policy specifies what rows to drop/remove based on missing column data

all: Drop the row if all columns are missing

any: Drop the row if any column is missing

threshold: Drop the column if threshold number of columns are missing

---

```

enum class io_format : unsigned char {
    csv = 1,
};

```

This specifies the I/O format for reading and writing to/from files, streams, etc.

Currently only CSV format is supported. The CSV format is as follows:

-- Any empty line or any line started with # will be ignored

-- A data line has the following format:

<column name>:<number of data points>:<\<type\>>:data,data,...

An example line would look like this:

price:1001:<double>:23.456,24.56,...

---

```

template<typename T, typename U>
struct type_declare;

```

```

template<typename U>
struct type_declare<HeteroVector, U> { using type = std::vector<U>; };

```

```

template<typename U>
struct type_declare<HeteroView, U> { using type = VectorView<U>; };

```

This is a spoofy way to declare a type at compile time dynamically. Here it is used in declaring a few different data structures depending whether we are a `DataFrame` or `DataFrameView`

---

```
template<typename TS, typename HETERO>
class DataFrame;
```

```
template<typename TS>
using StdDataFrame = DataFrame<TS, HeteroVector>;
```

```
template<typename TS>
using DataFrameView = DataFrame<TS, HeteroView>;
```

`DataFrame` is a class that has; An index column of type `TS` (timestamp, although it doesn't have to be time), and many other columns of different types. The storage used throughout is `std::vector`.

`DataFrames` could be instantiated in two different modes:

*StdDataFrame* is the standard fully functional data-frame.

*DataFrameView* is a referenced to a slice of another data-frame. Most of the functionalities of *StdDataFrame* is also available on the *DataFrameView*. But some functionalities such as adding/removing columns etc. are not allowable on views. If you change any of the data in a *DataFrameView* the corresponding data in the original *StdDataFrame* will also be changed.

---

## METHODS

*template<typename T>*  
*std::vector<T> &create\_column(const char \*name);*  
It creates an empty column named "name"

---

T: Type of the column  
Returns a reference to the vector for that column

---

*void remove\_column(const char \*name);*  
It removes a column named name.  
The actual data vector is not deleted, but the column is dropped from DataFrame

---

*void rename\_column (const char \*from, const char \*to);*  
It renames column named from to to. If column from does not exists, it throws an exception

---

*template<typename ... Ts>*  
*size\_type &load\_data(TSVec &&indices, Ts ... args);*  
This is the most generalized load function. It creates and loads an index and a variable number of columns. The index vector and all column vectors are "moved" to DataFrame.

Ts: The list of types for columns in args  
indices: A vector of indices (timestamps) of type TimeStamp;  
args: A variable list of arguments consisting of  
    std::pair(<const char \*name, std::vector<T> &&data>).  
    Each pair represents a column data and its name  
Returns number of items loaded

---

*template<typename ITR>*  
*size\_type load\_index(const ITR &begin, const ITR &end);*  
It copies the data from iterators begin to end into the index column

ITR: Type of the iterator  
Returns number of items loaded

---

*template<typename ITR>*  
*size\_type load\_index(const ITR &begin, const ITR &end);*  
It copies the data from iterators begin to end into the index column

ITR: Type of the iterator  
Returns number of items loaded

---

*size\_type load\_index(TSVec &&idx);*

It moves the idx vector into the index column.  
Returns number of items loaded

---

```
template<typename T, typename ITR>
size_type load_column(const char *name,
                    Index2D<const ITR &> range,
                    nan_policy padding = nan_policy::pad_with_nans);
```

It copies the data from iterators begin to end to the named column. If column does not exist, it will be created. If the column exist, it will be over written.

T: Type of data being copied  
ITR: Type of the iterator  
name: Name of the column  
range: The begin and end iterators for data  
padding: If true, it pads the data column with nan if it is shorter than the index column.  
Returns number of items loaded

---

```
template<typename T>
size_type
load_column(const char *name,
            std::vector<T> &&data,
            nan_policy padding = nan_policy::pad_with_nans);
```

It moves the data to the named column in DataFrame. If column does not exist, it will be created. If the column exist, it will be over written.

T: Type of data being moved  
name: Name of the column  
padding: If true, it pads the data column with nan, if it is shorter than the index column.  
Returns number of items loaded

---

```
size_type append_index(const TimeStamp &val);
```

It appends val to the end of the index column.  
Returns number of items loaded

---

```
template<typename T>
size_type append_column(const char *name,
                      const T &val,
                      nan_policy padding = nan_policy::pad_with_nans);
```

It appends val to the end of the named data column. If data column doesn't exist, it throws an exception.

T: Type of the named data column  
name: Name of the column  
padding: If true, it pads the data column with nan,

if it is shorter than the index column.  
Returns number of items loaded

---

`template<typename ITR>`  
`size_type append_index(Index2D<const ITR &> range);`  
It appends the range begin to end to the end of the index column

ITR: Type of the iterator  
range: The begin and end iterators for data  
Returns number of items loaded

---

`template<typename T, typename ITR>`  
`size_type append_column(const char *name,`  
`Index2D<const ITR &> range,`  
`nan_policy padding = nan_policy::pad_with_nans);`  
It appends the range begin to end to the end of the named data column. If data column doesn't exist, it throws an exception.

T: Type of the named data column  
ITR: Type of the iterator  
name: Name of the column  
range: The begin and end iterators for data  
padding: If true, it pads the data column with nan,  
if it is shorter than the index column.  
Returns number of items loaded

---

`template<typename ... types>`  
`void remove_data_by_idx (Index2D<TS> range);`  
It removes the data rows from index begin to index end.  
DataFrame must be sorted by index or behavior is undefined.  
This function first calls `make_consistent()` that may add nan values to data columns.

types: List all the types of all data columns.  
A type should be specified in the list only once.  
range: The begin and end iterators for index specified with index values

---

`template<typename ... types>`  
`void remove_data_by_loc (Index2D<int> range);`  
It removes the data rows from location begin to location end within range.  
This function supports Python-like negative indexing. That is why the range type is int.  
This function first calls `make_consistent()` that may add nan values to data columns.

types: List all the types of all data columns.

A type should be specified in the list only once.

range: The begin and end iterators for data

---

```
template<typename T, size_t N>
void fill_missing(const std::array<const char *, N> col_names,
                 fill_policy policy,
                 const std::array<T, N> values = { },
                 int limit = -1);
```

It fills all the "missing values" with the given values, and/or using the given method (See fill\_policy above). Missing is determined by being NaN for types that have NaN. For types without NaN (e.g. string), default value is considered missing value.

T: Type of the column(s) in col\_names array

N: Size of col\_names and values array

col\_names: An array of names specifying the columns to fill.

policy: Specifies the method to use to fill the missing values.

For example; forward fill, values, etc.

values: If the policy is "values", use these values to fill the missing holes. Each value corresponds to the same index in the col\_names array.

limit: Specifies how many values to fill. Default is -1 meaning fill all missing values.

---

```
template<typename ... types>
void drop_missing(drop_policy policy, size_type threshold = 0);
```

It removes a row if any or all or some of the columns are NaN, based on drop policy

types: List all the types of all data columns.

A type should be specified in the list only once.

threshold: If drop policy is threshold, it specifies the numbers of NaN columns before removing the row.

---

```
template<typename ... types>
void make_consistent ();
```

Make all data columns the same length as the index. If any data column is shorter than the index column, it will be padded by nan.

This is also called by sort(), before sorting

---

```
template<typename T, typename ... types>
void sort(const char *by_name = nullptr);
```

Sort the DataFrame by the named column. By default, it sorts by index (i.e.

by\_name == nullptr). Sort first calls make\_consistent() that may add nan values to data columns. nan values make sorting nondeterministic.

T: Type of the by\_name column. You always of the specify this type, even if it is being sorted to the default index

types: List all the types of all data columns.

A type should be specified in the list only once.

---

```
template<typename T, typename ... types>
std::future<void> sort_async (const char *by_name = nullptr);
```

Same as sort() above, but executed asynchronously

---

```
template<typename F, typename T, typename ... types>
DataFrame groupby (F &&func,
                  const char *gb_col_name = nullptr,
                  sort_state already_sorted = sort_state::not_sorted) const;
```

Groupby copies the DataFrame into a temp DataFrame and sorts the temp df by gb\_col\_name before performing groupby. If gb\_col\_name is null, it groups by index.

F: type functor to be applied to columns to group by

T: type of the groupby column. In case if index, it is type of index

types: List of the types of all data columns.

A type should be specified in the list only once.

func: The functor to do the groupby. Specs for the functor is in a separate doc.

already\_sorted: If the DataFrame is already sorted by gb\_col\_name, this will save the expensive sort operation

---

```
std::future<DataFrame>
groupby_async (F &&func,
              const char *gb_col_name = nullptr,
              sort_state already_sorted = sort_state::not_sorted) const;
```

Same as groupby() above, but executed asynchronously

---

```
template<typename T>
StdDataFrame<T> value_counts (const char *col_name) const;
```

It counts the unique values in the named column.

It returns a StdDataFrame of following specs:

- 1) The index is of type T and contains all unique values in the named column.
- 2) There is only one column named "counts" of type size\_type that contains the count for each index row.

For this method to compile and work, 3 conditions must be met:

- 1) Type T must be hashable. If this is a user defined type, you must enable and specialize std::hash.
- 2) The equality operator (==) must be well defined for type T.
- 3) Type T must match the actual type of the named column.

Of course, if you never call this method in your application, you need not be worried about these conditions.

T: Type of the col\_name column.

---

`template<typename F, typename ... types>`

`DataFrame bucketize (F &&func, const Timestamp &bucket_interval) const;`

It bucketizes the data and index into bucket\_interval's, based on index values and calls the functor for each bucket. The result of each bucket will be stored in a new DataFrame with same shape and returned. Every data bucket is guaranteed to be as wide as bucket\_interval. This mean some data items at the end may not be included in the new bucketized DataFrame. The index of each bucket will be the last index in the original DataFrame that is less than bucket\_interval away from the previous bucket

NOTE: The DataFrame must already be sorted by index.

F: type functor to be applied to columns to bucketize

types: List of the types of all data columns.

A type should be specified in the list only once.

bucket\_interval: Bucket interval is in the index's single value unit.

For example, if index is in minutes, bucket\_interval will be in the unit of minutes and so on.

already\_sorted: If the DataFrame is already sorted by index, this will save the expensive sort operation

---

`template<typename F, typename ... types>`

`std::future<DataFrame>`

`bucketize_async (F &&func, const Timestamp &bucket_interval) const;`

Same as bucketize() above, but executed asynchronously

---

`template<typename F, typename ... types>`

`void self_bucketize (F &&func, const Timestamp &bucket_interval);`

This is exactly the same as bucketize() above. The only difference is it stores the result in itself and returns void. So, after the return the original data is lost and replaced with bucketized data

---

`template<typename T, typename V>`

`DataFrame transpose(TSVec &&indices,`

`const V &current_col_order,`

`const V &new_col_names) const;`

It transposes the data in the DataFrame.

The transpose() is only defined for DataFrame's that have a single data type.

NOTE: Since DataFrame columns have no ordering, the user must specify the order with current\_col\_order.

T: The single type for all data columns  
V: The type of string vector specifying the new names for new columns after transpose  
indices: A vector on indices for the new transposed DataFrame.  
Its length must equal the number of rows in this DataFrame.  
Otherwise an exception is thrown  
current\_col\_order: A vector of strings specifying the order of columns in the original DataFrame.  
new\_col\_names: A vector of strings, specifying the column names for the new transposed DataFrame.  
Its length must equal the number of rows in this DataFrame. Otherwise an exception is thrown

---

`template<typename RHS_T, typename ... types>  
StdDataFrame<TS> join_by_index (const RHS_T &rhs, join_policy mp) const;`

It joins the data between self (lhs) and rhs and returns the joined data in a StdDataFrame, based on specification in join\_policy.

The following conditions must be met for this method to compile and work properly:

- 1) TS type must be the same between lhs and rhs.
- 2) Ordering (< > != ==) must be well defined for type TS
- 3) Both lhs and rhs must be sorted by index
- 4) In both lhs and rhs, columns with the same name must have the same
- 5) Type

RHS\_T: Type of DataFrame rhs

types: List all the types of all data columns.

A type should be specified in the list only once.

rhs: The rhs DataFrame

join\_policy: Specifies how to join. For example inner join, or left join, etc. (See join\_policy definition)

---

`template<typename ... types>`

`void self_shift (size_type periods, shift_policy sp);`

It shifts all the columns in self up or down based on shift\_policy.

Values that are shifted will be assigned to NaN. The index column remains unchanged.

If user shifts with periods that is larger than the column length, all values in that column become NaN.

types: List all the types of all data columns.

A type should be specified in the list only once.

periods: Number of periods to shift

shift\_policy: Specifies the direction (i.e. up/down) to shift

---

`template<typename ... types>`

It is exactly the same as `self_shift`, but it leaves `self` unchanged and returns a new `DataFrame` with columns shifted.

If user rotates with periods that is larger than the column length, the behavior is undefined.

**shift\_policy:** Specifies the direction (i.e. up/down) to rotate

It is exactly the same as `self.rotate`, but it leaves `self` unchanged and returns a new `DataFrame` with columns rotated.

<Column2 name>:<Column2 type>:<Comma delimited list of values>

**iof:** Specifies the I/O format. The default is CSV

Same as write() above, but executed asynchronously

INDEX:<Comma delimited list of values>

<Column1 name>:<Column1 type>:<Comma delimited list of values>  
<Column2 name>:<Column2 type>:<Comma delimited list of values>  
All empty lines or lines starting with # will be skipped.

file\_name: Complete path to the file

iof: Specifies the I/O format. The default is CSV

---

```
std::future<bool> read_async (const char *file_name,  
                             io_format iof = io_format::csv);
```

Same as read() above, but executed asynchronously

---

```
template<typename T>  
typename type_declare<HETERO, T>::type &  
get_column (const char *name);
```

It returns a reference to the container of named data column

The return type depends on if we are in standard or view mode

T: Data type of the named column

---

```
template<typename T>  
const typename type_declare<HETERO, T>::type &  
get_column (const char *name) const;
```

It returns a const reference to the container of named data column

The return type depends on if we are in standard or view mode

T: Data type of the named column

---

```
template<size_t N, typename ... types>  
HeteroVector
```

```
get_row(size_type row_num, const std::array<const char *, N> col_names) const;
```

It returns the data in row row\_num for columns in col\_names. The order of data items in the returned vector is the same as order of columns on col\_names.

The first item in the returned vector is always the index value corresponding to the row\_num

It returns a HeteroVector which contains a different type for each column.

N: Size of col\_names and values array

types: List all the types of all data columns. A type should be specified in the list only once.

row\_num: The row number

col\_names: Names of columns to get data from. It also specifies the order of data in the returned vector

---

```
template<typename T>  
std::vector<T> get_col_unique_values (const char *name) const;
```

It returns a vector of unique values in the named column in the same

order that exists in the column.

For this method to compile and work, 3 conditions must be met:

- 1) Type T must be hash-able. If this is a user defined type, you must enable and specialize `std::hash`.
- 2) The equality operator (`==`) must be well defined for type T.
- 3) Type T must match the actual type of the named column.

Of course, if you never call this method in your application, you need not be worried about these conditions.

T: Data type of the named column

---

`template<typename ... types>`

`DataFrame get_data_by_idx (Index2D<TS> range) const;`

It returns a DataFrame (including the index and data columns) containing the data from index begin to index end. This function assumes the DataFrame is consistent and sorted by index. The behavior is undefined otherwise.

types: List all the types of all data columns.

A type should be specified in the list only once.

range: The begin and end iterators for index specified with index values

---

`template<typename ... types>`

`DataFrameView<TS> get_view_by_idx (Index2D<TS> range) const;`

It behaves like `get_data_by_idx()`, but it returns a DataFrameView.

A view is a DataFrame that is a reference to the original DataFrame.

So if you modify anything in the view the original DataFrame will also be modified.

Note: There are certain operations that you cannot do with a view.

For example, you cannot add/delete columns, etc.

types: List all the types of all data columns.

A type should be specified in the list only once.

range: The begin and end iterators for index specified with index values

---

`template<typename ... types>`

`DataFrame get_data_by_loc (Index2D<int> range) const;`

It returns a DataFrame (including the index and data columns) containing the data from location begin to location end.

This function supports Python-like negative indexing. That is why the range type is `int`.

This function assumes the DataFrame is consistent and sorted by index. The behavior is undefined otherwise.

types: List all the types of all data columns.

A type should be specified in the list only once.

range: The begin and end iterators for data

---

```
template<typename ... types>
```

```
DataFrameView<TS> get_view_by_loc (Index2D<int> range) const;
```

It behaves like `get_data_by_loc()`, but it returns a `DataFrameView`.

A view is a `DataFrame` that is a reference to the original `DataFrame`.

So if you modify anything in the view the original `DataFrame` will also be modified.

Note: There are certain operations that you cannot do with a view.

For example, you cannot add/delete columns, etc.

types: List all the types of all data columns.

A type should be specified in the list only once.

range: The begin and end iterators for data

---

```
const TSVec &get_index () const { return (indices_); }
```

It returns a const reference to the index container

---

```
TSVec &get_index () { return (indices_); }
```

It returns a reference to the index container

---

```
template<typename ... Ts>
```

```
void multi_visit (Ts ... args);
```

This is the most generalized visit function. It visits multiple columns with the corresponding function objects sequentially. Each function object is passed every single value of the given column along with its name and the corresponding index value. All functions objects must have this signature

```
bool (const TimeStamp &i, const char *name, T &col_value)
```

If the function object returns false, the `DataFrame` will stop iterating at that point on that column..

NOTE: This method could be used to implement a pivot table.

Ts: The list of types for columns in args

args: A variable list of arguments consisting of

```
std::pair(<const char *name,
```

```
&std::function<bool (const TimeStamp &, const char *, T &)>).
```

Each pair represents a column name and the functor to run on it.

NOTE: The second member of pair is a `_pointer_` to the function or functor object

---

```
template<typename T, typename V>
```

```
V &visit (const char *name, V &visitor);
```

It passes the values of each index and each named column to the functor visitor sequentially from beginning to end

NOTE: This method could be used to implement a pivot table.

T: Type of the named column

V: Type of the visitor functor  
name: Name of the data column

---

`template<typename T1, typename T2, typename V>`

`V &visit (const char *name1, const char *name2, V &visitor);`

It passes the values of each index and the two named columns to the functor visitor sequentially from beginning to end

NOTE: This method could be used to implement a pivot table.

T1: Type of the first named column

T2: Type of the second named column

V: Type of the visitor functor

name1: Name of the first data column

name2: Name of the second data column

---

`template<typename T1, typename T2, typename T3, typename V>`

`V &visit (const char *name1, const char *name2, const char *name3, V &visitor);`

It passes the values of each index and the three named columns to the functor visitor sequentially from beginning to end

NOTE: This method could be used to implement a pivot table.

T1: Type of the first named column

T2: Type of the second named column

T3: Type of the third named column

V: Type of the visitor functor

name1: Name of the first data column

name2: Name of the second data column

name3: Name of the third data column

---

`template<typename T1, typename T2, typename T3, typename T4, typename V>`

`V &visit (const char *name1,  
          const char *name2,  
          const char *name3,  
          const char *name4,  
          V &visitor);`

It passes the values of each index and the four named columns to the functor visitor sequentially from beginning to end

NOTE: This method could be used to implement a pivot table.

T1: Type of the first named column

T2: Type of the second named column

T3: Type of the third named column

T4: Type of the forth named column

V: Type of the visitor functor

name1: Name of the first data column

name2: Name of the second data column

name3: Name of the third data column  
name4: Name of the fourth data column

---

```
template<typename T1, typename T2, typename T3, typename T4, typename T5,  
        typename V>  
V &visit (const char *name1,  
         const char *name2,  
         const char *name3,  
         const char *name4,  
         const char *name5,  
         V &visitor);
```

It passes the values of each index and the five named columns to the functor visitor sequentially from beginning to end

NOTE: This method could be used to implement a pivot table.

T1: Type of the first named column  
T2: Type of the second named column  
T3: Type of the third named column  
T4: Type of the forth named column  
T5: Type of the fifth named column  
V: Type of the visitor functor  
name1: Name of the first data column  
name2: Name of the second data column  
name3: Name of the third data column  
name4: Name of the forth data column  
name5: Name of the fifth data column

---

```
template<typename T, typename V>  
V &single_act_visit (const char *name, V &visitor);
```

This is similar to visit(), but it passes a const reference to the index vector and the named column vector at once the functor visitor. This is convenient for calculations that need the whole data vector, for example auto-correlation.

T: Type of the named column  
V: Type of the visitor functor  
name: Name of the data column

---

```
template<typename T1, typename T2, typename V>  
V &single_act_visit (const char *name1, const char *name2, V &visitor);
```

This is similar to visit(), but it passes a const reference to the index vector and the two named column vectors at once the functor visitor. This is convenient for calculations that need the whole data vector.

NOTE: This method could be used to implement a pivot table.

T1: Type of the first named column  
T2: Type of the second named column

V: Type of the visitor functor  
name1: Name of the first data column  
name2: Name of the second data column

---

`template<typename ... types>`

`bool is_equal (const DataFrame &rhs) const;`

It compares self with rhs. If both have the same indices, same number of columns, same names for each column, and all columns are equal, then it returns true. Otherwise it returns false

types: List all the types of all data columns.  
A type should be specified in the list only once.

---

`template<typename ... types>`

`DataFrame &modify_by_idx (DataFrame &rhs,  
sort_state already_sorted = sort_state::not_sorted);`

It iterates over all indices in rhs and modifies all the data columns in self that correspond to the given index value. If not already\_sorted, both rhs and self will be sorted by index. It returns a reference to self

types: List all the types of all data columns.  
A type should be specified in the list only once.  
already\_sorted: If the self and rhs are already sorted by index,  
this will save the expensive sort operations

---

## GLOBAL OPERATORS

These are currently arithmetic operators declared in *include/DataFrame.h*. Because they all have to be templated, they cannot be defined as redefined built-in operators.

```
template<typename DF, typename ... types>  
inline DF df_plus (const DF &lhs, const DF &rhs);
```

```
template<typename DF, typename ... types>  
inline DF df_minus (const DF &lhs, const DF &rhs);
```

```
template<typename DF, typename ... types>  
inline DF df_multiplies (const DF &lhs, const DF &rhs);
```

```
template<typename DF, typename ... types>  
inline DF df_divides (const DF &lhs, const DF &rhs);
```

These arithmetic operations operate on the same-name and same-type columns on lhs and rhs. Each pair of entries is operated on, only if they have the same index value.

They return a new DataFrame

NOTE: Both lhs and rhs must be already sorted by index, otherwise the result is nonsensical.

---

## BUILT-IN VISITORS

These are all defined in file *include/DataFrameVisitors.h*.

```
template<typename T,  
        typename TS_T = unsigned long,  
        typename = typename std::enable_if<std::is_arithmetic<T>::value, T>::type>  
struct MeanVisitor;
```

This functor class calculates the mean of a given column. See this document and `datasci_tester.cc` for examples.

T: Column/data type

TS\_T: Index type

*T must be an arithmetic-enabled type*

---

```
template<typename T,  
        typename TS_T = unsigned long,  
        typename = typename std::enable_if<std::is_arithmetic<T>::value, T>::type>  
struct SumVisitor;
```

This functor class calculates the sum of a given column. See this document and `datasci_tester.cc` for examples.

T: Column/data type

TS\_T: Index type

*T must be an arithmetic-enabled type*

---

```
template<typename T, typename TS_T = unsigned long>  
struct MaxVisitor;
```

This functor class calculates the maximum of a given column. See this document and `datasci_tester.cc` for examples.

T: Column/data type

TS\_T: Index type

---

```
template<typename T, typename TS_T = unsigned long>  
struct MinVisitor;
```

This functor class calculates the minimum of a given column. See this document and `datasci_tester.cc` for examples.

T: Column/data type

TS\_T: Index type

---

```
template<std::size_t N, typename T, typename TS_T = unsigned long>  
struct NLargestVisitor;
```

This functor class calculates the N largest values of a column. It runs in  $O(N \cdot M)$ , where N is the number of largest values and M is the total number of all values. If N is relatively small this is better than  $O(M \cdot \log M)$ .

See this document and `datasci_tester.cc` for examples.

N: Number of largest values

T: Column/data type

TS\_T: Index type

---

```
template<std::size_t N, typename T, typename TS_T = unsigned long>
struct NSmallestVisitor;
```

This functor class calculates the N smallest values of a column. It runs in  $O(N*M)$ , where N is the number of largest values and M is the total number of all values.

If N is relatively small this is better than  $O(M*\log M)$ .

See this document and `datasci_tester.cc` for examples.

N: Number of largest values

T: Column/data type

TS\_T: Index type

---

```
template<typename T,
        typename TS_T = unsigned long,
        typename = typename std::enable_if<std::is_arithmetic<T>::value, T>::type>
struct CovVisitor;
```

This functor class calculates the covariance of two given columns. In addition, it provides the variances of both columns

See this document and `datasci_tester.cc` for examples.

T: Column/data type

TS\_T: Index type

*T must be an arithmetic-enabled type*

---

```
template<typename T,
        typename TS_T = unsigned long,
        typename = typename std::enable_if<std::is_arithmetic<T>::value, T>::type>
struct VarVisitor;
```

This functor class calculates the variance of a given column. See this document and `datasci_tester.cc` for examples.

T: Column/data type

TS\_T: Index type

*T must be an arithmetic-enabled type*

---

```
template<typename T,
        typename TS_T = unsigned long,
        typename = typename std::enable_if<std::is_arithmetic<T>::value, T>::type>
struct StdVisitor;
```

This functor class calculates the standard deviation of a given column. See this document and `datasci_tester.cc` for examples.

T: Column/data type  
TS\_T: Index type  
*T must be an arithmetic-enabled type*

---

```
template<typename T,  
        typename TS_T = unsigned long,  
        typename = typename std::enable_if<std::is_arithmetic<T>::value, T>::type>  
struct CorrVisitor;
```

This functor class calculates the correlation of two given columns. See this document and datasci\_tester.cc for examples.

T: Column/data type  
TS\_T: Index type  
*T must be an arithmetic-enabled type*

---

```
template<typename T,  
        typename TS_T = unsigned long,  
        typename = typename std::enable_if<std::is_arithmetic<T>::value, T>::type>  
struct AutoCorrVisitor;
```

This functor class calculates the auto correlation of given column. The result is a vector of auto correlations with lags of 0 up to length of column – 4. See this document and datasci\_tester.cc for examples.

T: Column/data type  
TS\_T: Index type  
*T must be an arithmetic-enabled type*

---

```
template<typename T,  
        typename TS_T = unsigned long,  
        typename = typename std::enable_if<std::is_arithmetic<T>::value, T>::type>  
struct DotProdVisitor;
```

This functor class calculates the dot-product of two given columns. See this document and datasci\_tester.cc for examples.

T: Column/data type  
TS\_T: Index type  
*T must be an arithmetic-enabled type*

---

```
template<typename T,  
        typename TS_T = unsigned long,  
        typename = typename std::enable_if<std::is_arithmetic<T>::value, T>::type>  
struct StatsVisitor;
```

This functor class calculates the following statistics of a given column; mean, variance, standard deviation, skew, and kurtosis. See this document and datasci\_tester.cc for examples.

T: Column/data type

TS\_T: Index type

*T must be an arithmetic-enabled type*

---

```
template<typename T,  
        typename TS_T = unsigned long,  
        typename = typename std::enable_if<std::is_arithmetic<T>::value, T>::type>  
struct SLRRegressionVisitor;
```

This functor class calculates simple linear regression, in one pass, of two given columns (x, y). See this document and datasci\_tester.cc for examples.

T: Column/data type

TS\_T: Index type

*T must be an arithmetic-enabled type*

---
